*Inspiring Awe & Wonder*

The “diffuse” sensitivity of a neutrino observatory is  
**the sensitivity to a uniform all-sky flux of astrophysical or cosmogenic neutrinos,**  
as opposed to a particular object (source) at a particular point in the sky.

Diffuse source (of light)

Point source (of light)

*Astrophysical* neutrinos:  
Produced in interactions near the  
sources of high energy Cosmic Rays.  
The sum of lots of blurry sources forms  
a diffuse flux.

*Cosmogenic* neutrinos:  
Produced in collisions of UHE  
Cosmic Rays with background light.

- IceCube has characterized the astrophysical flux from TeV to PeV energies.
- At EHE energies (many PeV and above), IceCube and Auger have placed limits.
- KM3NeT recently saw an EHE event...?

We estimate our sensitivity to the diffuse flux using a few different quantities:

|                          |                           |                                                                                  |
|--------------------------|---------------------------|----------------------------------------------------------------------------------|
| Effective Aperture       | Area $\times$ Solid Angle | How effective are we at observing neutrinos of a given energy?                   |
| Expected event rate      | Counts                    | How many neutrinos do we expect to observe if we assume a given flux?            |
| Differential sensitivity | Flux                      | What's the smallest possible flux we could detect, i.e. see X events in Y years? |

Aperture  $A\Omega \simeq [\text{instrumented area}] \times [\text{useful solid angle}] \times [\text{probability neutrino} \rightarrow \text{tau}]$

IceCube:  $\sim 500\text{m}^2\text{sr}$  at 1PeV

$\sim 1$

$\sim 4 \times 10^{-6}$ , at 1PeV

What have we previously computed?

In our 2026 Nature Astronomy Perspective, we published our  $\nu_\tau$  aperture, computed by Pavel + Will based on 2025 simulation.

The calculation used:

- Simulated site = Valley of the Volcanoes, rescaled to 5000 detectors from 700
- 4m<sup>2</sup> panel areas
- Trigger/cut conditions =
  - At least 3 modules with at least 3 hits
  - At least 30 hits total
  - At least 4km of rock overburden

$$A\Omega(1\text{PeV}) \simeq 50\text{m}^2\text{sr}$$

$$A\Omega(10\text{PeV}) \simeq 200\text{m}^2\text{sr}$$

We also computed our differential sensitivity with the same 2025 simulation.

Note: there are some outstanding revisions for this plot I have not had a chance to make! These include:

- Fixing all curves to use the same spectral convention (IC EHE uses  $E^{-1}$ , Auger uses  $E^{-2}$ )
- Cosmetic changes to axis and legend labels
- Cosmetic changes to IceCube measurements

As well as event rates based on different assumed flux models:

Note: there are some outstanding revisions for this plot I have not had a chance to make! These include:

- Annotating the total count in the top right
- Visually differentiate different classes of models
- Cosmetic changes to axis and legend labels

The 2025 simulation used an early draft of TamboSim.jl.  
Since then we have made the following improvements:

- Added ability to differentiate sensor efficiencies to shower particles of different species / energies, based on GEANT4\*
- Greatly improved interface for weighting, and (re)processing
- Correct treatment of the terrain in Julia and in CORSIKA, which was particularly important for backgrounds and timing-dependent studies
- Added CR backgrounds
- Added muon backgrounds and muon-neutrino signals\*

\*Not yet integrated into the main branch, but coming soon

What results can we produce using 2026 simulation (TamboSim-v1) instead of 2025?

- We can use more realistic descriptions of the sensors (size, particle efficiency)
- We can describe rates and distributions at different processing and filter levels
- We can include background simulations (CRs, muons) and thus better motivate our signal purity
- We could include other neutrino flavors ( $\nu_\mu$ )

Some newer results using TamboSim-v1:  
[work in progress]

## Valley of the Volcanoes

- Instrumented area  $\approx 13\text{km}^2$
- Inclination  $\sim 30^\circ$

## Valley of the Volcanoes

- Instrumented area  $\approx 13\text{km}^2$
- Inclination  $\sim 30^\circ$

# Valley of the Volcanoes: 2026 simulation results (4m<sup>2</sup> panels, 900 modules / 13km<sup>2</sup> area — not rescaled)

- injection level → 118.4 m<sup>2</sup> sr at 1 PeV
- only decays in air → 19.0 m<sup>2</sup> sr at 1 PeV
- shower reaches obs. surface → 48.8 m<sup>2</sup> sr at 1 PeV
- $\geq 5$  modules with  $\geq 1$  hits → 14.7 m<sup>2</sup> sr at 1 PeV
- $\geq 3$  modules with  $\geq 3$  hits → 12.2 m<sup>2</sup> sr at 1 PeV
- $\geq 5$  modules with  $\geq 1$  hits (no  $\gamma$ ) → 10.1 m<sup>2</sup> sr at 1 PeV

Energy deposition curves, for:

- 1cm thick Fermilab scintillator
- 1mm aluminum housing.

- Above  $\sim 100\text{MeV}$ , **gammas** have a  $\sim 3\%$  probability of depositing  $\sim 2\text{MeV}$  of energy (via pair production)
- Above  $\sim 5\text{MeV}$ , **muons** and **electrons** have a  $\sim 100\%$  probability of depositing  $\sim 2\text{MeV}$  of energy

Valley of the Volcanoes: 2026 simulation results  
(4m<sup>2</sup> panels, 900 modules / 13km<sup>2</sup> area — not rescaled)

Tau neutrinos:  
directionally dependent  
effective area, at 1-10PeV

Valley of the Volcanoes: 2026 simulation results  
(4m<sup>2</sup> panels, 900 modules / 13km<sup>2</sup> area — not rescaled)

Cosmic Ray protons:  
directionally dependent  
effective area, at 0.1-1PeV

## Conclusions:

- Aperture computed with 2026 simulation (TamboSim-v1) is consistent with 2025 results
- TamboSim-v1 enables us to treat sensor modules more realistically and to do further studies of triggers, cuts, directional reconstruction, and backgrounds
